ABSTRACT

Inflammation contributes to the pathogenesis of acute kidney injury (AKI). IL-33 is a proinflammatory cytokine, but its role in AKI is unknown. Here we observed increased protein expression of full-length IL-33 in the kidney following induction of AKI with cisplatin. To determine whether IL-33 promotes injury, we administered soluble ST2 (sST2), a fusion protein that neutralizes IL-33 activity by acting as a decoy receptor. Compared with cisplatin-induced AKI in untreated mice, mice treated with sST2 had fewer CD4 T cells infiltrate the kidney, lower serum creatinine, and reduced acute tubular necrosis (ATN) and apoptosis. In contrast, administration of recombinant IL-33 (rIL-33) exacerbated cisplatin-induced AKI, measured by an increase in CD4 T cell infiltration, serum creatinine, ATN, and apoptosis; this did not occur in CD4-deficient mice, suggesting that CD4 T cells mediate the injurious effect of IL-33. Wildtype mice that received cisplatin and rIL-33 also had higher levels of the proinflammatory chemokine CXCL1, which CD T cells produce, in the kidney compared with CD4-deficient mice. Mice deficient in the CXCL1 receptor also had lower serum creatinine, ATN, and apoptosis than wildtype mice following cisplatin-induced AKI. Taken together, IL-33 promotes AKI through CD4 T cell-mediated production of CXCL1. These data suggest that inhibiting IL-33 or CXCL1 may have therapeutic potential in AKI.

Cisplatin and other platinum derivatives are important chemotherapeutic agents used to treat solid tumors, including ovarian, head and neck, and testicular germ cell tumors.1 A known complication of cisplatin administration is acute kidney injury (AKI).2 The nephrotoxic effect of cisplatin is cumulative and dose-dependent and often necessitates dose reduction or withdrawal.1 Therefore, an understanding of the pathogenesis of cisplatin-induced AKI is important for the development of therapies to prevent this complication.

We have demonstrated that there is proximal tubular apoptosis and necrosis, and a massive increase, in both proinflammatory caspase-1 and proapoptotic caspase-3 in the kidney in cisplatin-induced AKI in mice.3 IL-33 is a proinflammatory cytokine.4 It has been proposed that IL-33 is released from necrotic cells, binds the ST2R on immune cells, and increases secretion of cytokines, with resultant inflammation.5 In apoptosis, caspase-3 cleaves and lessens IL-33 binding to the ST2R.5–8 As IL-33 is modulated by necrosis and apoptosis, and increases in necrosis and apoptosis are features of cisplatin-induced AKI, we determined the effect of cisplatin on IL-33 in mice.

The role of inflammation in AKI is gaining prominence; specifically, CD4 T-cell inflammation has been described to play an injurious role in cisplatin-induced AKI in mice.10 IL-33 is known to be a chemoattractant for CD4 T cells via the

As inflammation with CD4 T cells is a feature of cisplatin-induced AKI, we propose that IL-33 induces CD4 T-cell infiltration in the kidney, with resultant kidney injury. Thus, we developed the hypothesis that injection of sST2, a fusion protein that neutralizes IL-33 activity by acting as a decoy receptor, would be protective against cisplatin-induced AKI by reducing CD4 T cell infiltration in the kidney.

On this background, we sought to determine the role of IL-33 in cisplatin-induced AKI. We hypothesize that IL-33 plays an injurious role in cisplatin-induced AKI. The role of IL-33 has not previously been described in any kidney disease.

RESULTS

Results are on day 3 after cisplatin (25 mg/kg), unless otherwise specified.

Serum IL-33
Serum IL-33, measured by enzyme-linked immunosorbent assay (ELISA), was significantly increased on day 2 compared with vehicle, days 1 and 3 (Figure 1). The increase in serum IL-33 on day 2 preceded the significant increase in serum creatinine that occurs on day 3 after cisplatin (see Methods). IL-33 was undetectable in the urine by ELISA. The lack of IL-33 in the serum on day 3 and the further increase in IL-33 on day 3 in the kidney suggest that the kidney is not a major source of serum IL-33.

Immunofluorescence for IL-33
Immunofluorescence for IL-33 in the kidney was performed in vehicle-treated mice. On double staining for IL-33 and lectin, IL-33 was clearly seen in glomeruli and also in peritubular areas (Figure 2, A). To determine whether the IL-33 staining in glomeruli and peritubular areas was in endothelium, double IF staining for IL-33 and von Willebrand factor (vWF) was performed. IL-33 co-localized with vWF in glomeruli and in peritubular capillaries (arrows) in cortex (B) and outer stripe of outer medulla (C). (D) Staining for vascular α-smooth muscle actin (green) and IL-33 (red) demonstrates IL-33 staining on the endothelial surface of blood vessels.

Microvascular Endothelial Cells
To determine whether cisplatin causes release of IL-33 in vitro, microvascular endothelial cells in culture were studied. Microvascular endothelial cells were treated with 10 μM cisplatin to induce apoptosis and 50 μM cisplatin to induce necrosis. Full-length (34 kD) IL-33 increased in the medium of endo-
thelial cells treated with 50 μM cisplatin compared with endothelial cells treated with the vehicle (Figure 4). No cleaved IL-33 was detected in the medium.

Evan’s Blue Dye In Vivo Leakage Assay
To determine whether cisplatin causes vascular injury in vivo, an Evan’s blue dye in vivo leakage assay was performed, as described in the Methods section. There was increased leakage of dye in the lung on day 2, and in the kidney on days 1 and 2, of cisplatin-induced AKI compared with vehicle-treated controls. Evan’s blue dye in the lung (μg/g of lung weight) was 183.7 ± 16.8 in vehicle-treated mice and 287.7 ± 14.1 on day 2 of cisplatin-induced AKI (P < 0.01 versus vehicle-treated mice; n = 5 per group). Evan’s blue dye in the kidney (μg/g of kidney weight) was 58.9 ± 3.0 in vehicle-treated mice, 77.3 ± 4.0 on day 1, and 108.1 ± 4.0 on day 2 of cisplatin-induced AKI (P < 0.05 versus vehicle-treated mice, P < 0.01 versus vehicle-treated mice, P < 0.05 versus day 1; n = 5 to 7 per group).

Soluble ST2 (sST2) Injection
To determine whether inhibition of IL-33 protects against cisplatin-induced AKI, mice were injected with soluble ST2 (sST2), a fusion protein that neutralizes IL-33 activity by acting as a decoy receptor. Mice with cisplatin-induced AKI injected with sST2 had a significant decrease in creatinine (Figure 5, A), ATN score (Figure 5, B), and number of apoptotic tubular cells (Figure 5, C).

To determine whether inhibition of IL-33 increases survival in cisplatin-induced AKI, mice were injected with sST2 or vehicle on days 1, 2, and 3 after cisplatin injection. On day 4 of cisplatin-induced AKI, 0/10 vehicle-treated mice survived, whereas 3/6 sST2-treated mice survived (P < 0.05). On day 5, 0/6 sST2-treated mice survived. The model of cisplatin-induced AKI is a severe and irreversible model of cisplatin-toxicity. On day 4 after cisplatin injection, mice become severely systemically ill, do not eat or drink, and require sacrifice. The exact cause of death is not known. In addition to AKI, cisplatin also causes liver injury, gastrointestinal ulcerations, myocardial injury, lung injury, and neurotoxicity in animals.16–19 Thus, it is possible that the mice died of other organ toxicities in addition to AKI. While sST2 protected against cisplatin-induced AKI on day 3, injection of sST2 did not provide protection against the severe systemic toxicity of cisplatin.

IL-33 Injection
Injection of rIL-33 into wildtype mice had no effect on serum creatinine or infiltration of CD4 T cells into the kidney on flow cytometry. To determine if rIL-33 aggravated cisplatin-induced AKI, mice were injected with a lower dose of cisplatin (15 mg/kg) that causes a smaller increase in serum creatinine.

Figure 3. Cisplatin increases IL-33. (A) On ELISA of whole kidney, IL-33 was increased on days 1, 2, and 3 of cisplatin-induced AKI. *P < 0.05 compared with vehicle-treated (Veh); **P < 0.01 versus Veh. (B) On immunoblot of whole kidney, there was an increase in both the full-length (34 kD) and cleaved (22 kD) IL-33 on days 2 and 3 of cisplatin-induced AKI. (C) On ELISA of nuclear extracts of whole kidney, IL-33 was increased on days 1, 2, and 3 of cisplatin-induced AKI. *P < 0.001 compared with vehicle-treated (Veh). (D) On immunoblot of nuclear extracts of whole kidney, there was an increase in the full-length (34 kD) IL-33 on day 1, 2, and 3 and cleaved (22 kD) IL-33 on day 3 of cisplatin-induced AKI. Representative immunoblots of at least three independent experiments are demonstrated. Equal protein loading was confirmed by staining the same membrane for actin (43 kD) or the nuclear protein Lamin A (69 kD).

Figure 4. In cisplatin-treated endothelial cells, there is release of the full-length IL-33 into the medium. Microvascular endothelial cells were treated with 10 μM cisplatin that we have described to induce apoptosis and 50 μM cisplatin that produces necrosis.15 On immunoblot of the medium of the cisplatin-treated endothelial cells, there was an increase in the full-length (34 kD) IL-33 with 50 μM cisplatin compared with vehicle-treated. Pos = positive control: recombinant cleaved IL-33 (22 kD). *P < 0.05 versus vehicle (Veh) and Cisplatin 10 μM (Cis 10); n = 3 per group.
than we have described with 25 mg/kg cisplatin. Injection of rIL-33 plus cisplatin (15 mg/kg) caused an increase in serum creatinine, ATN score, and apoptosis score compared with injection of cisplatin (15 mg/kg) alone (Figure 6, A, B, and C). The increase of serum creatinine, ATN score, and apoptosis score with injection of rIL-33 plus cisplatin (15 mg/kg) was not seen in CD4 T-cell-deficient mice (Figure 6, A, B, and C).

**Flow Cytometry for CD4 T Cells**

CD4 T cells were absent in spleens of CD4−/− mice compared with wildtype mice. In the kidney, the number of CD4 positive cells as a percentage of total live cells is shown in Figure 7, A. In wildtype kidneys, CD4 T cells were increased with cisplatin (25 mg/kg) treatment on days 1, 2, and 3 compared with vehicle treatment alone. Injection of rIL-33 plus cisplatin (15 mg/kg) resulted in a significant increase in CD4 T cells in the kidney compared with cisplatin (15 mg/kg) alone. CD4 T cells in the kidney were absent in CD4−/− mice treated with cisplatin.3 We have previously demonstrated that neutrophil depletion in the kidney using the neutrophil-depleting antibody RB6–8C5 is not protective against cisplatin-induced AKI.20

ST2 is known to be expressed on Th2 but not Th1 cells.11 Flow cytometry for CD4 and ST2 was performed in the kidney. In vehicle-treated mice, the percentage of CD4 T cells that were also ST2 positive was 48% ± 10 (n = 3). On day 3 after cisplatin, the percentage of CD4 T cells that were also ST2 positive was 97% ± 1 (%) (n = 3). Thus, most of the CD4 T cells detected on flow cytometry in the kidney in cisplatin-induced AKI were also ST2 positive, indicating that these cells were Th2 CD4 T cells.

The number of neutrophils in the kidney is increased by rIL-33 added to low-dose cisplatin. The number of neutrophils per high power field (hpf) on day 3 was 0 in vehicle-treated mice, 0.02 in mice treated with cisplatin 15 mg/kg, and 13.4 in mice treated with cisplatin 15 mg/kg plus rIL-33 (P < 0.001 versus vehicle and cisplatin 15 mg/kg, n = 5 to 13 per group). The number of neutrophils in the kidney in cisplatin-induced AKI is decreased by injection of sST2. The number of neutrophils per hpf on day 3 was 0 in vehicle-treated mice, 2.4 in mice treated with cisplatin 25 mg/kg (P < 0.01 versus vehicle-treated), and 0.02 in mice treated with cisplatin 25 mg/kg plus sST2 (P < 0.01 versus cisplatin 25 mg/kg, n = 5 to 13 per group). In our model of cisplatin-induced AKI, neutrophils are undetectable in the kidney in vehicle-treated mice and on days 1 and 2 after cisplatin.3 In addition, renal myeloperoxidase (MPO) activity in the kidney was found to be very low (less than 0.05 OD/min/mg protein) and was not significantly different between vehicle-treated mice and on days 1 and 2 after cisplatin.3

**Depletion of CD4 T cells**

To confirm the role of CD4 T cells in cisplatin-induced AKI, mice were depleted of CD4 T cells. Mice depleted of CD4 T cells (CD4−/− mice or GK1.4 antibody injection) had less cisplatin-induced AKI, demonstrating the role of CD4 T cells in cisplatin-induced AKI. CD4−/− mice treated with cisplatin had significantly lower creatinine (Figure 8, A) and apoptosis scores (Figure 8, C) than wildtype mice treated with...
cisplatin. The ATN score in CD4−/− mice treated with cisplatin (Figure 8, B) was lower than wildtype mice treated with cisplatin but did not reach statistical significance. Mice treated with GK1.5 antibody plus cisplatin had a significantly lower creatinine than mice treated with cisplatin plus vehicle (Figure 8, D).

**CXCL1 (Also Known as IL-8 or KC)**

CD4 T cells produce CXCL1. CXCL1 was increased in the kidney by day 2 after cisplatin (Figure 9, A). CXCL1 was increased in wildtype mice but not in CD4 T cell−/− mice treated with low-dose cisplatin (15 mg/kg) plus rIL-33 (Figure 9, B). The increase in CXCL1 in cisplatin-induced AKI was decreased in CD4 T cell−/− mice (Figure 9, C). IL-33 does not increase CXCL1 in normal mice. IL-33 (pg/mg) was 18.7 ± 7.1 in vehicle-treated wildtype mice and 19.0 ± 2.7 in mice treated with rIL-33 (n = 3, P > 0.05). To demonstrate that CXCL1 is a mediator of cisplatin-induced AKI, CXCR2−/− mice that lack the receptor for CXCL1 were studied. CXCR2 is not specific for CXCL1 and binds other Glu-leu-Arg ELR+ CXC chemokines like CXCL2 (MIP-2).21,22 However, CXCL2 has a lower affinity for CXCR2 than CXCL1 and is less able to initiate signal transduction and a biologic effect than CXCL1.21,22 CXCR2−/− mice with cisplatin-induced AKI had a significantly lower creatinine (Figure 9, D), ATN score (Figure 9, E), and apoptosis score (Figure 9, F) in tubular cells compared with wildtype mice with cisplatin-induced AKI.

To further establish a link between IL-33, CD4 T cells, and CXCL1, the effect of rIL-33 on CD4 T cells in vitro to produce...
CXCL1 was performed as described in the Methods. In vitro, rIL-33 stimulated CD4 T cells to produce CXCL1. CXCL1 was higher in cisplatin-treated CD4 T cells compared with vehicle-treated CD4 T cells. rIL-33 did not result in a further increase in CXCL1 in cisplatin-treated CD4 T cells. CXCL1 (pg/mg) was 4.0 in vehicle-treated CD4 T cells, 12.3 in rIL-33-treated CD4 T cells (P < 0.01 versus vehicle-treated), 11.0 in cisplatin-treated CD4 T cells (P < 0.01 versus vehicle-treated), and 12.0 in cisplatin plus rIL-33-treated CD4 T cells (P < 0.01 versus vehicle-treated; n = 3 per group). We have previously demonstrated the presence of CXCL1 in mouse kidneys in proximal tubules and macrophages in the outer stripe of the outer medulla. The in vitro experiment demonstrates CXCL1 in normal CD4 T cells and an increase in CXCL1 in CD4 T cells treated with rIL-33.

**Figure 8.** Depletion of CD4 T cells protects against cisplatin-induced AKI. CD4−/− mice treated with cisplatin (CD4−/− Cis) had a significantly lower (A) creatinine and (C) apoptosis score than wildtype mice treated with cisplatin (WT Cis). (B) The ATN score in CD4−/− mice treated with cisplatin (CD4−/− Cis) was lower than wildtype mice treated with cisplatin (WT Cis) but did not reach statistical significance. (D) Mice treated with GK1.5 antibody plus cisplatin (GK1.5 Cis) had a significantly lower creatinine than mice treated with cisplatin plus vehicle (Veh Cis). *P < 0.001 versus Veh; **P < 0.05 versus WTCis or VehCis; n = 4 to 8 per group.

**Time Sequence of Events in Cisplatin-Induced AKI**

Figure 10 demonstrates the time sequence of events in cisplatin-induced AKI.

**DISCUSSION**

The IL-33/ST2 pathway has been described as a novel biomarker in vascular injury as well as a therapeutic target. Serum levels of ST2 predict mortality and clinical outcome after acute myocardial infarction and are a biomarker of worsening heart failure. Serum IL-33 levels are increased in patients with active rheumatoid arthritis. Serum levels of IL-33 were increased in mice with cisplatin-induced AKI, suggesting diffuse endothelial injury due to cisplatin. The increase in serum IL-33 preceded the increase in ATN and serum creatinine. In this regard, we have previously demonstrated that serum von Willebrand factor, also a marker of endothelial injury, is also increased on day 2 in mice with cisplatin-induced AKI. Also, vascular injury (e.g., thrombotic microangiopathy) has been reported in patients receiving cisplatin. In the present study, we demonstrate leakage of Evan’s blue dye from the blood vessels into the kidney on days 1 and 2 after cisplatin. Thus, serum ST2 or IL-33 as a biomarker of vascular injury in cisplatin-induced AKI merits further investigation.

Next we determined the localization of IL-33 in the kidney. IL-33 was predominantly expressed in glomeruli, blood vessels, and peritubular capillaries in the kidney. Next we determined the intracellular localization of IL-33 in the kidney. IL-33 is identical to nuclear factor expressed in high endothelial venules (NF-HEV). In the nucleus may activate the transcription factor AP-1 as well as nuclear factor–kappa B (NF-κB). Thus, IL-33 serves as an intracellular nuclear factor with transcriptional regulatory properties as well as a proinflammatory cytokine. The present study demonstrates that IL-33 in the kidney is predominantly expressed in nuclear extracts. The exact function of IL-33 in the nucleus has not been established.

When cells undergo caspase-3-mediated apoptosis, caspase-3 cleaves IL-33 into a less active cleaved form (22 kD on immunoblot). We think that the predominant process in cisplatin-induced AKI is an increase in synthesis of the full-length form of IL-33 rather than caspase-3 cleavage of IL-33 into a less active form. Evidence for the former is as follows: (1) an increase of the full-length form of IL-33 on day 1 rather than the cleaved form of IL-33 in the kidney (Figure 3, D), (2) release of full-length IL-33 rather than cleaved IL-33 into the medium of endothelial cells (Figure 4), and (3) if IL-33 were being predominantly cleaved and inactivated by caspase-3, then IL-33 would not be injurious. Specific IL-33 inhibition is protective against cisplatin-induced AKI, demonstrating the injurious role of IL-33 (Figure 5). A recent study demonstrates that calpain can also cleave IL-33 into a less active form. However, we have demonstrated an increase in calpain activity in cisplatin-treated endothelial cells. We also demonstrated that calpain causes endothelial necrosis, as calpain inhibition is protective against cisplatin-induced necrosis, suggesting that calpain-mediated inactivation of IL-33 is not the dominant process in cisplatin-treated endothelial cells. The present study is unique, as it demonstrates that there is an increase in IL-33 protein in cisplatin-induced AKI in vivo. IL-33 has also been described as a cytokine mainly involved in allergic inflammation and asthma. The present study is also unique in that it demonstrates an effect of a nonimmune stimulus, cisplatin, on IL-33.
To demonstrate the injurious role of IL-33, mice injected with rIL-33 had worse cisplatin-induced AKI, and mice injected with soluble sST2, a fusion protein that neutralizes IL-33 activity by acting as a decoy receptor, had a significant reduction in cisplatin-induced AKI. Next we determined the effect of IL-33 on inflammation in the kidney. The role of inflammation in AKI is gaining prominence.9 Our published data in cisplatin-induced AKI demonstrate that although there is an increase in neutrophils and macrophages in the kidney, neither neutrophil nor macrophage depletion is protective.20,29 It has been demonstrated that CD4 T cell mice are functionally and histologically protected against cisplatin-induced AKI.10,35 The major proinflammatory effect of IL-33 is to induce CD4 T-cell Th2 cell responses via the ST2R.11 In the present study, we demonstrate that administration of rIL-33 worsens cisplatin-induced AKI in wildtype but not CD4 T cell−/− mice, suggesting that IL-33-mediated injury is dependent on CD4 T cells. To confirm the injurious role of IL-33 in cisplatin-induced AKI, mice were injected with soluble ST2 (sST2), a fusion protein that neutralizes IL-33 activity by acting as a decoy receptor. Injection of sST2 significantly reduced the number of CD4 T cells in the kidney in cisplatin-induced AKI and protected against cisplatin-induced AKI. To confirm the injurious effect of CD4 T cells, CD4 T cell−/− mice or injection of the GK1.5 antibody was protective against cisplatin-induced AKI. Renal TNF-α, IL-1β, and CXCL1 are increased in cisplatin-induced AKI.10 IL-1β inhibition is not protective against cisplatin-induced AKI.20 TNF-α inhibition has been shown to be a mediator of cisplatin-induced AKI.36,37 TNF-α promotes caspase-1 activation via the inflammasome.38 The major effect of CXCL1 is to cause neutrophil recruitment. The exact role of neutrophils in AKI is controversial.9,20,39 However, in addition to neutrophil recruitment, CXCL1 can directly induce apoptosis of cells in vitro via release of intracellular Ca, FasL expression.40 Thus, the injurious effect of CXCL1 in cisplatin-induced AKI may be related to neutrophil recruitment or direct effects on other cell types.

Figure 9. CXCR2−/− mice are protected against cisplatin-induced AKI. (A) CXCL1 was increased in the kidney by day 2 after cisplatin (Cis day 2). *P < 0.01 versus vehicle (Veh) and day 1 after cisplatin (Cis day 1). (B) rIL-33 injection in wildtype mice (WT + IL-33) did not increase CXCL1 compared with vehicle injection in wildtype mice (WT Veh). CXCL1 was significantly higher in wildtype mice treated with low-dose cisplatin (15 mg/kg; WT Cis) compared with wildtype mice treated with the vehicle for cisplatin (WT Veh). CXCL1 was increased in wildtype mice treated with low-dose cisplatin (15 mg/kg) plus rIL-33 (WT Cis IL33) compared with wildtype mice treated with low-dose cisplatin (15 mg/kg) alone (WT Cis). The increase in CXCL1 seen in wildtype mice treated with low-dose cisplatin (WT Cis) and wildtype mice treated with low-dose cisplatin plus rIL-33 (WT Cis IL33) was not seen in CD4 T cell−/− mice treated with low-dose cisplatin (CD4−/− Cis) or low-dose cisplatin plus rIL-33 (CD4−/− Cis IL33). **P < 0.001 versus all other groups; *P < 0.01 versus Veh. (C) The increase in CXCL1 in cisplatin-treated (25 mg/kg) wildtype mice AKI (WT Cis) was decreased in cisplatin-treated CD4 T cell−/− mice (CD4−/− Cis). *P < 0.001 versus vehicle-treated (Veh) and CD4−/− Cis. (D–F) CXCR2−/− mice (CR2−/−) that lack the receptor for CXCL1 have significantly lower creatinine, ATN score, and apoptosis in tubular cells compared with cisplatin-treated wildtype mice (WT Cis). *P < 0.001 versus Veh; **P < 0.01 versus WT Cis; n = 4 per group.
Figure 10. Time sequence of events in cisplatin-induced AKI. There is ATN and tubular apoptosis on day 2 and ATN and renal failure on day 3 of cisplatin-induced AKI. There is increased neutrophil infiltration on day 3 but not on days 1 and 2 of cisplatin-induced AKI. There is increased macrophage infiltration on day 2. In the present study, we demonstrate increased IL-33 in the kidney on days 1, 2, and 3; increased CD4 T cell infiltration in the kidney on days 1, 2, and 3; and increased CXCL1 in the kidney on days 2 and 3. The increase in IL-33 on day 1 precedes the ATN, tubular apoptosis, inflammation, and renal failure. Mφ, macrophage; BUN, blood urea nitrogen; SCR, serum creatinine.

CONCISE METHODS

Cisplatin Administration
For all of the mouse studies, 8- to 10-wk-old male C57BL/6 mice weighing 20 to 25 g were used. All experiments were conducted with adherence to the National Institutes of Health Guide for the Care and Use of Laboratory Animals. The animal protocol was approved by the Animal Care and Use Committee of the University of Colorado Health Sciences Center. Mice were maintained on a standard diet, and water was freely available. Mice were housed five per cage under a 12-h light-and-dark schedule for at least 1 wk before cisplatin administration. Six hours before cisplatin administration, food and water were withheld. Cisplatin (cis-Diamminedichloro-platinum [II]; Aldrich, Milwaukee, WI) was freshly prepared on the day of administration in sterile normal saline at a concentration of 1 mg/mL. Mice were given either 25 mg/kg or 15 mg/kg body wt of cisplatin or vehicle (saline) intraperitoneally, after which the mice again had free access to food and water.

We described this model of cisplatin-induced ARF in detail elsewhere. Briefly, after 25 mg/kg cisplatin injection, blood urea nitrogen (BUN) and serum creatinine are normal on day 1 and slightly increased on day 2. On day 3 after cisplatin injection, renal dysfunction, renal neutrophil infiltration, and acute tubular necrosis scores are severe. Serum creatinine, ATN score, and apoptosis score on day 3 are increased after cisplatin (15 mg/kg; Figure 6, A, B, and C) but are significantly lower compared with 25 mg/kg (Figure 5, A, B, and C).

Histologic Examination
Paraformaldehyde (4%-fixed and paraffin-embedded kidneys were sectioned at 4 μm and stained with periodic acid-Schiff (PAS) by standard methods. All histologic examinations were performed by the renal pathologist in a blinded fashion. Histologic changes due to acute tubular necrosis (ATN score) were evaluated in the outer stripe of the outer medulla on PAS-stained tissue and were quantified by counting the percent of tubules that displayed cell necrosis, loss of brush border, cast formation and tubule dilation, as follows: 0 = none, 1 = <10%, 2 = 10 to 25%, 3 = 26 to 45%, 4 = 46 to 75%, and 5 = >75%. At least 10 fields (×250) were reviewed for each slide.

Neutrophil infiltration was quantitatively assessed on PAS-stained tissue by the renal pathologist by counting the number of neutrophils per high power field (×400), as we have previously described. At least 10 fields were counted in the outer stripe of the outer medulla for each slide.

Morphologic criteria were used to count apoptotic cells on PAS-stained tissue by the pathologist experienced in the evaluation of renal apoptosis. Morphologic characteristics included cellular rounding and shrinkage, nuclear chromatin compaction, and formation of apoptotic bodies. Apoptotic tubular cells were quantitatively assessed per 10 high-power fields (×400) in the outer stripe of the outer medulla by the renal pathologist in a blinded fashion.

Endothelial Cells in Culture
MS1 (MILE SVEN 1) mouse endothelial pancreatic islet cells were purchased from American Type Culture Collection (ATCC®, Manassas, VA; catalog no. CRL-2279). The line retains the properties of endothelial cells, including uptake of acetylated LDL and expression of both factor-VIII-related antigen and VEGFR. Cells were grown in Dulbecco’s Modified Eagle’s Medium (DMEM). Experiments were performed when the plates became at least 80% confluent.

We have described the model of cisplatin-induced injury to microvascular endothelial cells in detail elsewhere. Briefly, cells treated with 10 μM of cisplatin demonstrate apoptosis, and cells treated with 50 μM cisplatin demonstrate necrosis. After cisplatin treatment, the medium was removed from the cells. Proteins in the medium of the cells were precipitated using trichloroacetic acid (TCA).
IL-33 and CXCL1 ELISA
Both the mouse IL-33 ELISA (catalog no. M3300) and CXCL1/KC ELISA (catalog no. MKC 008) kits were obtained from R&D Systems (Minneapolis, MN). ELISA was performed according to the manufacturer’s instructions.

Nuclear Extracts
Nuclear extracts of whole kidney were prepared from fresh kidney using a NE-PER Nuclear and cytoplasmic extraction kit (Thermo Scientific). Nuclear extracts were immunoblotted with the nuclear protein Lamin A (Santa Cruz Biotechnology, Santa Cruz, CA) (catalog no. sc-20681) as a loading control.

Immunoblot Analysis
Whole kidney was homogenized in radioimmunoprecipitation assay (RIPA) buffer plus protease inhibitors and immunoblotted, as described previously. A monoclonal Ab (Nessy-1) that recognizes mouse, human, and rat full-length IL-33 (34 kD) and the cleaved IL-33 (22 kD) was used (catalog no. ALX-804-840, Alexis Biochemicals, San Diego, CA). Mouse rIL-33, amino acids Ser109-Ile266, was used as a positive control (BioLegend, San Diego, CA). A rabbit polyclonal antibody raised against amino acids 76 to 375 of actin of human origin (43 kD) was used as a loading control (catalog no. sc-10731, Santa Cruz Biotechnology, Santa Cruz, CA).

Immunofluorescence Studies
Kidney tissues were embedded in OCT, snap-frozen in liquid nitrogen, and stored at −80°C until sectioning. Five-μm cryostat sections were fixed in 70% acetone/30% methanol and prepared for immunofluorescence studies, as described previously. A monoclonal Ab (Nessy-1) that recognizes mouse, human, and rat full-length IL-33 (34 kD) and the cleaved IL-33 (22 kD) was used (catalog no. ALX-804-840, Alexis Biochemicals, San Diego, CA). A rabbit polyclonal antibody to VWF, which specifically reacts with the cytoplasm of endothelial cells, was used (Abcam, Cambridge, MA; catalog no. ab6994). An Alexa Fluor 488 conjugate of wheat germ agglutinin, a widely used lectin, was obtained from Invitrogen (Carlsbad, CA; catalog no. W11261). A fluorescein isothiocyanate (FITC) conjugated monoclonal anti-α-smooth muscle actin antibody was obtained from Sigma (St. Louis, MO; product no. F3777).

IL-33 Administration
One μg of mouse rIL-33, amino acids Ser109-Ile266, (BioLegend, San Diego, CA) or vehicle (PBS) was injected intraperitoneally, twice a day, on days 1, 2, and 3 after cisplatin administration. The same dose and route of administration of rIL-33 has been demonstrated to reduce the development of atherosclerosis in mice.

Mouse T-cell CD4 Isolation
Splenoocytes from C57BL/6 mice were crushed in culture dishes to obtain a single-cell suspension. The splenoocytes were resuspended in cold RPMI, and red blood cells (RBCs) were lysed using ACK lysis buffer (Quality Biologic, Inc.). The resulting suspension was filtered through a sterile cell strainer (70μm) to remove cellular debris, washed twice with phosphate-buffered saline (PBS) and counted. T cells were enriched by passing splenocyte suspensions over a T-cell CD4 Subset column kit (R&D Systems, catalog no. MCD4C-1000). The purity of the population was confirmed by flow cytometry analysis and routinely reached >90%.

CD4 T cells were resuspended in appropriate volume of RPMI with 0.5% fetal calf serum and 100 U/ml penicillin, and 100 U/ml streptomycin. CD4 T cells were incubated at 37°C and 5% CO2 during 24 h, with 2000pg/ml of recombinant murine IL-33 or vehicle control (0.1% BSA in 1x PBS). To avoid cytokine release to the media, CD4 T cells were treated with Brefeldin A (eBiosciences) for the last 8 h of the incubation. CXCL1 production by CD4+ cells was performed by a CXCL1/KC ELISA kit (catalog no. MKC 008) obtained from R&D Systems (Minneapolis, MN) as per the manufacturer’s instruction and corrected for protein. The detection limit of CXCL1 is 2.0 pg/ml.

sST2 Administration
The sST2 fusion protein (muST2-huFc) was obtained from Dirk Smith (Amgen, Seattle, WA). Administration and dose of sST2 was based on previous studies. One hundred μg of sST2 in PBS or vehicle (hu IgG Fc control) was administered on days 1, 2, and 3 of cisplatin administration.

GK1.5 Antibody Administration
GK1.5 monoclonal antibody was obtained from Bioxcell (West Lebanon, NH). Mice were injected with 10 mg/kg of the rat IgG monoclonal antibody GK1.5 intraperitoneally on days −7 and −2 before cisplatin administration. Administration of the GK1.5 antibody is known to result in CD4 T cell depletion. We have previously demonstrated the effect of GK1.5 to cause CD4 T cell depletion in lymph nodes and kidneys. Control animals received 10mg/kg intraperitoneally of the rat IgG (Sigma) at the same time points.

Flow Cytometry
To determine the effect of cisplatin on CD4 T cell population, flow cytometric detection of CD45, CD3, and CD4 was performed on fresh samples of spleen and kidney, as described in detail. The samples were incubated with following antibodies: (1) per-CP conjugated anti-CD45 (eBioscience, catalog no. 45-0451-80); (2) APC conjugated anti-CD4 (catalog no. 11-0033-81); (3) PE conjugated anti-CD3 (catalog no. 11-0033-81). Samples were first gated for live cells. Of the live cells, high FITC signals were gated for CD45+ events. CD45+ events were set as gating limit at 10,000 events, and 15,000 events for kidney and spleen, respectively. High PE signals were gated for CD3+ events, and, of that, population high APC signal events were analyzed, which represent CD4+ cells.

CD4 T cell −/− and CXCR2 −/− mice
Mice homozygous for the CD4 tm1Mak targeted mutation in the C57BL/6 strain were obtained from the Jackson Laboratory. Cell surface expression of CD4 protein is not detected on thymocytes and lymph nodes from homozygous mice. Age-, weight-, and sex-matched C57BL/6 mice were used as controls. Mice homozygous for the CXCR2 mutation in the C57BL/6 strain were obtained by breeding and genotyping heterozygous mice obtained from the Jackson Laboratory.
Laboratory, as described.45,46 Age-, sex-, and weight-matched litter- 
mates were used as controls.

In Vivo Leakage Assay
Mice were injected with Evan’s blue dye, combined with albumin, via 
the tail vein. After 60 min, in separate experiments, the lung was 
perfused with normal saline via the right ventricle on day 2 after cis-
platin, or the kidney was perfused with normal saline via the left ven-
tricle on days 1 and 2 after cisplatin. When endothelial permeability is 
increased, the dye extravasates and reaches the subendothelial spaces. 
Thus, subsequent washing of dye-perfused organs with saline cannot 
remove the dye. After perfusion, the lung or kidneys were removed, 
homogenized, and centrifuged. Spectrophotometric analysis of su-
pernatants for Evan’s blue dye, at 540 nm, was then performed. The 
difference in optical density values is indicative of the increase in dye 
retention, hence, of vascular leakage.

Statistical Analysis
Non-normally distributed data were analyzed by the nonparametric 
unpaired Mann-Whitney test. Multiple group comparisons are per-
formed using ANOVA, with posttest according to Newman-Keuls. 
For the survival study, a contingency table for survival on day 4 was 
analyzed by Fisher’s exact test. A P value of <0.05 was considered 
statistically significant. Values are expressed as means ± SEM.
