ABSTRACT

Idiopathic nephrotic syndrome resistant to standard treatments remains a therapeutic dilemma in pediatric nephrology. To test whether the anti-CD20 monoclonal antibody rituximab may benefit these patients, we conducted an open-label, randomized, controlled trial in 31 children with idiopathic nephrotic syndrome unresponsive to the combination of calcineurin inhibitors and prednisone. All children continued prednisone and calcineurin inhibitors at the doses prescribed before enrollment, and one treatment group received two doses of rituximab (375 mg/m² intravenously) as add-on therapy. The mean age was 8 years (range, 2–16 years). Rituximab did not reduce proteinuria at 3 months (change, −12% [95% confidence interval, −73% to 110%]; P=0.77 in analysis of covariance model adjusted for baseline proteinuria). Additional adjustment for previous remission and interaction terms (treatment by baseline proteinuria and treatment by previous remission) did not change the results. In conclusion, these data do not support the addition of rituximab to prednisone and calcineurin inhibitors in children with resistant idiopathic nephrotic syndrome.

Idiopathic nephrotic syndrome (INS) in children is a continuum of clinical disorders characterized by severe proteinuria, hypoalbuminemia, dyslipidemia, and hypercoagulability. INS includes pathologic variants that feature polymorphic podocyte injury as a unifying feature.1–3 Disease mechanisms are poorly understood, with the exception of the most severe cases, which are caused by molecular defects of one of the podocyte genes.4–7 For nongenetic forms of INS, responsiveness to prednisone alone or in combination with calcineurin inhibitors8,9 is the most important prognostic criterion to distinguish progressive from nonprogressive entities, given the known fibrogenic properties of persisting proteinuria.10,11

The chimeric monoclonal anti-CD20 antibody rituximab has recently emerged as a potential novel therapy for INS. Rituximab was first proposed for Hodgkin lymphoma and autoimmune diseases.12–17

Our group recently reported that rituximab successfully maintained short-term remission of proteinuria in children with INS responding to and dependent on both prednisone and calcineurin inhibitor, thereby allowing discontinuation of these standard medications.18

Anecdotal cases and few uncontrolled studies in small cohorts suggest that rituximab may induce disease remission in forms of INS unresponsive to prednisone and calcineurin inhibitors.19,20 The present multicenter randomized trial tested this hypothesis by comparing rituximab and the standard approach based on prednisone and calcineurin inhibitors in resistant forms of INS.

RESULTS

Patient Characteristics

Between 2007 and 2010, we screened 157 children with INS and enrolled 31 eligible patients at four pediatric nephrology centers. Sixteen were randomly assigned to receive rituximab in double doses in addition to prednisone and calcineurin inhibitors and were compared with 15 patients randomly assigned to standard therapy (Figure 1). Baseline characteristics are summarized in Table 1. Children were on average 8 years of age and had a disease duration of 1.5 years. At randomization, all children were treated with prednisone (median dosage, 0.42 mg/kg per day [range, 0.1–1.9 mg/kg per day]), and most were receiving calcineurin inhibitors at the minimum oral amount necessary to achieve trough levels: 50–100 ng/ml for cyclosporine and 5–10 ng/ml for tacrolimus. In three cases, calcineurin inhibitors had been stopped 1 month before the start of the run-in period because of severe hypertension.

All children had a history of resistance to both drugs that had lasted at least the 6 months before randomization (range, 6 months to 11.8 years; median, 1.3 years) (Table 1). Fifteen patients had developed resistance to treatments months or years after disease onset, during which time they had become dependent on steroids and calcineurin inhibitors. Thus, they were defined as “delayed resistant.” Development of unresponsiveness started at least 6 months before randomization. Children with delayed resistance were similarly represented in both treatment groups (Table 1).

At the time of enrollment, average prednisone and calcineurin inhibitor doses did not differ between groups. Additional therapies (angiotensin-receptor blocker and angiotensin-converting enzyme inhibitors) were used in the same proportions of patients. All clinical measures, including baseline proteinuria, kidney function, serum albumin, and cholesterol, were similar in the two groups.

Pharmacokinetics

Data on rituximab kinetics were measured in seven children at baseline and after the first infusion (Supplemental Table 1). Median serum levels were 0 μg/ml at the first infusion of rituximab, 313.4 μg/ml 15 minutes after infusion (range, 103.2–333 μg/ml), and 215.7 μg/ml 24 hours after infusion (range, 67.2–417.4 μg/ml). Similar levels were observed at the second infusion. The trend of serum levels of the patients analyzed was similar to that observed in previous studies in adults with clinical conditions requiring rituximab.21

Effectiveness

Figure 2 shows the distribution of proteinuria and prednisone dosage by group assignment over time (medians and interquartile ranges) and the proportion of patients receiving full doses of calcineurin inhibitors. Geometric mean values of proteinuria at baseline and study end were, respectively, 2.7 (95% confidence interval [CI], 1.7–4.2) g/d per m² and 1.8 (95% CI, 0.9–3.4) g/d per m² among controls and
2.4 (95% CI, 1.7–3.5) g/d per m² and 1.4 (95% CI, 0.9–2.8) g/d per m² among children assigned to rituximab. Six delayed-resistant patients (equally distributed by randomization group) achieved remission of proteinuria (Table 2). The doses of prednisone and calcium calcineurin inhibitor were reduced in these patients during the study.

Table 2 reports data on proteinuria, serum albumin levels, and creatinine levels by treatment group and history of previous responsiveness. Table 3 summarizes the results of regression analysis of log-transformed proteinuria. Rituximab did not reduce proteinuria after 3 months (model 1; analysis of covariance model adjusted for baseline proteinuria). The effect was larger but still nonsignificant in patients who had responded to standard therapy in the past and became resistant later (model 2; prespecified secondary analysis). No other factor (including histologic findings) affected the outcome or modified the effect of rituximab. CD20 counts were reduced to <1% at the first month in all rituximab-treated patients. After 3 months, CD20 count was still undetectable in all but one case. After 3 months, patients in the control group were offered alternative therapies, including plasmapheresis and protein A pheresis. Patients assigned to rituximab were monitored for an additional 3 months, and daily proteinuria did not change (geometric mean, 1.36 [95% CI, 0.65–2.87] g/d per m²). These patients were monitored for safety assessment for another 12 months.

Adverse Events

Acute Adverse Events

One patient developed a severe reaction with bronchospasm and hypotension during the second rituximab infusion; treatment was discontinued and the patient spontaneously recovered. Another child had a severe acute allergic reaction to the bolus of chlorpheniramine maleate during the premedication therapy. The child had extreme dizziness, skin rash, and bronchospasm, and the protocol was stopped (without any infusion of rituximab). Other minor side effects were more frequent and consisted of abdominal pain (four cases), skin rash (three cases), and mild dyspnea (two cases). Resolution was rapidly and completely achieved in all cases by reducing the infusion rate.

Delayed Adverse Events

After 18-month follow-up, no important side effects were observed.

DISCUSSION

The potential use of anti-CD20 antibodies (rituximab) in children with INS has recently emerged from uncontrolled observations and a randomized, controlled trial in children with INS dependent on both steroids and calcineurin inhibitors. Although the pathogenesis of INS is not fully understood, recent observations on potential mechanisms suggest that rituximab may be a possible therapeutic option for patients with INS who are unresponsive to calcineurin inhibitors and steroids and therefore have no other therapeutic options.

First, rituximab interacts with regulatory elements of the Fas, TGF-β, and NF-kB pathways. Second, rituximab affects regulatory elements of B cell differentiation, proliferation, and function. Third, rituximab reduces expression of soluble cytokines and chemokines, including TNF-α and IL-10.

Finally, preliminary observations suggest that rituximab reduces expression of soluble urokinase-type plasminogen activator receptor by monocytes (Ghiggeri, personal observation). This is of particular
importance because this receptor has recently been identified as a circulating factor that plays a direct pathogenetic role in FSGS by interacting with αvβ3 integrin.32,33 However, evidence from randomized, controlled trials is necessary to promote its use in clinical practice.

To our knowledge, this is the first randomized, controlled trial in children with INS unresponsive to standard combination therapy with calcineurin inhibitors and prednisone.34 The study indicates that two intravenous doses of rituximab do not change 3-month proteinuria by the hypothesized amount (70% reduction) compared with the standard approach. The trend of serum levels of rituximab in patients analyzed was not influenced by nephrotic syndrome per se, and levels were similar to those observed in previous studies in adults with autoimmune disorders.21 Although the treatment appears to be safe in the short term, acute and potentially harmful allergic reactions may occur. Although midterm side effects did not occur, long-term follow-up safety data are warranted. Our study population included patients with delayed resistant forms of the disease, reflecting the heterogeneity of the population of children with INS. Although in this latter group the point estimate of the treatment effect was clinically more relevant (reduction of proteinuria with amelioration of serum albumin), results were similarly nonsignificant. This aspect may reflect important pathogenetic differences between children who are resistant ab initio and those with delayed resistance. Overall, our study indicates that rituximab should not be considered an alternative therapy in children unresponsive to steroids and calcineurin inhibitors, especially in those unresponsive ab initio.

Few data in the literature are available on the use of rituximab in patients with persistent resistance to the classic combination of prednisone and calcineurin inhibitors. A short series reported by Fernandez-Fresneda et al.23 showed no effect in six of eight patients and a partial response in the remaining two patients after four or six treatments. Gulati et al.20 reported complete remission in a variable number of patients, including those with delayed-resistant INS. Enrollment of delayed-resistant cases may partly explain these positive results, which we could not confirm. Thus, a randomized, controlled trial should be done to assess this topic.

A possible explanation of the negative results of our study is related to the current limited knowledge and understanding of the disease. Although molecular analysis of NPHS2 and WT1 allowed the identification and exclusion of the most severe forms of known genetic disorders, other genetically mediated forms of INS may have been included in our cohort of stable unresponsive children.6,34 In this respect, it is possible that delayed-resistant forms of INS (half of the sample of the present trial) may benefit from antibody-based therapies, including rituximab.

The list of renal genes involved in resistant forms of INS is now growing (up to 12 already characterized), and it is currently difficult to perform a systematic analysis. When only two genes are considered (NPHS2 and WT1), the estimated prevalence of genetic forms of INS in patients without a familial history of the disease indicates that as many as 15%–20% of cases carry a causative mutation.35 The prevalence of other genetic mutations resulting in INS unresponsive to available drugs (including rituximab) is unknown. Although we searched for the preceding two major genes involved in INS before enrollment, we cannot exclude the possibility that some patients may carry genetic disorders that could clinically affect outcomes. In this view, genes involved in dominant INS (INF2 and ACTN4) were not tested because patients with a family history (indicating a dominant trait) were not included in the study. Among recessive variants, only some of the participants were screened for CD2AP and TRCP6, which are responsible for rare cases with recessive inheritance. However, the incidence of CD2AP and TRCP6 in our database of 400 cases of INS is less than 2%.36,37 The development of next-generation techniques for molecular analysis will enable a more comprehensive analysis of all genes potentially involved in INS and

characterization of patient populations in whom new therapies may be successful.

Our study has limitations. First, we powered the study to detect a large effect (70% reduction of proteinuria at 3 months); false-negative results cannot be excluded, especially if a true effect exists and is smaller. We chose such a large effect size to detect a large effect (70% reduction of proteinuria at 3 months) is in place. Moreover, as a result of severe clinical conditions and therapy side effects, patients in the control group were offered alternative therapies, including plasmapheresis and protein Apheresis, because we considered further delays in treatment to be unethical. Thus, possibilities for prolonging the study protocol were limited. Patients assigned to rituximab were monitored for an additional 15 months to exclude delayed effects.

Third, we chose two infusions on the basis of recent observations of the effect of rituximab in patients with INS who have the same characteristics as our cohort.20 Those findings indicated that in patients in whom rituximab therapy was successful, remission of proteinuria was achievable at 3 months. Moreover, a result of severe characterization of patient populations in whom new therapies may be successful.

In conclusion, our study suggests that rituximab is not effective in forms of INS resistant to steroids and calcineurin inhibitors. This seems to be especially true in children with INS who never responded to standard drugs. Further studies may be necessary in children with delayed-resistant forms of INS. An improvement in the basic molecular work-up for genetic disorders causing INS is necessary to better characterize the target population of new therapies for INS.

CONCISE METHODS

Design Overview

Eligible participants entered a 1-month run-in period during which proteinuria was monitored and adherence assessed. During the run-in period, instructions on urine collection and dipstick readings were carefully reviewed. After run-in, children were centrally allocated to continue standard therapy alone or to have rituximab added, independent of the current level of proteinuria. Allocation was concealed by contacting the holder of the allocation schedule at central administration at the University of Calgary, Calgary, Alberta, Canada (P.R.). Random sequences were generated using R software (version 2.13.1). Assignments followed permuted block randomization with blocks of variable size. Clinical investigators, study nurses enrolling patients, and the statistician were not blinded to group assignment. However, study staff responsible for facilitating follow-up data measurements by contacting patient families by phone were kept blinded. An independent data safety monitoring board reviewed safety data when half the participants had been enrolled and at study end. The protocol and consent documents were approved by the ethics committees at each participating center (EudraCT 2007-007796-16). All patients provided written informed consent.

Setting and Participants

Participants in this study had to be 16 years of age or younger and have an estimated creatinine clearance >60 ml/min per 1.73 m². They had to have a history of INS unresponsive to the combination of prednisone and calcineurin inhibitors for at least 6 months. INS was defined by the presence of nephrotic-range proteinuria (>40 mg/m² per hour or >1 g/d per m²) or a protein-to-creatinine ratio (>4 mg/mg in a single urine specimen) associated with low serum albumin (<2.5 g/dl) and high cholesterol (>220 mg/dl); in case of lower proteinuria values (5–40 mg/m² per hour), the association with hypoalbinemia and dyslipidemia was considered sufficient for the definition of INS. Children could be enrolled once drug unresponsiveness had persisted for at least 45 days with full-dose steroids (60 mg/m²), three pulses of methylprednisolone (10 mg/kg) given every other day, and 100 days of combination therapy with full doses of prednisone (2 mg/kg) and calcineurin inhibitors (cyclosporine, 5 mg/kg tacrolimus, 0.1 mg/kg). A 1-month run-in period followed this 5-month clinical history, for an overall period of drug resistance of at least 6 months. Overall, the interval of drug resistance was 2 years (median) and ranged from 6 months to 11.8 years (Table 1). Fifteen patients were classified as delayed-resistant because they had developed drug resistance after a phase of responsiveness to and dependence on both steroids and calcineurin inhibitors. These patients were randomly assigned after 6-month unresponsiveness was documented.

Negative results on genetic testing for NPHS2 and WTI were required in all cases. Exclusion criteria were infantile onset (<1 year); previous episodes of macrohematuria; hepatitis B virus, hepatitis C virus, or HIV infection; positivity for any marker of autoimmunity (antineutrophil antibody, nuclear DNA, antineutrophil cytoplasmic antibody); and low C3 levels. Renal biopsy had to be performed in children who never responded to steroids and calcineurin inhibitors (Table 1).

Common therapies for nephrotic syndrome, such as diuretics, anticoagulant therapy, angiotensin-converting enzyme inhibitors, or angiotensin-receptor blockers, were used at the discretion of the investigators but were kept constant during the study (Table 1).

Intervention Strategy and Standard Therapy

The intervention strategy was based on rituximab (Mabthera), 375 mg/m², given intravenously twice (at randomization and after 2 weeks). The medication was diluted in normal saline (1 mg/ml) and administered at increasing speeds (0.5–1.5 ml/min) over approximately 6 hours, in the absence of side effects. The infusion was preceded by chlorpheniramine maleate, 2.5–5 mg intravenously; methylprednisolone, 2 mg/kg in normal saline intravenously; and paracetamol, 8 mg/kg orally. Children in both groups had to continue prednisone (median, 0.42 mg/kg per day) and calcineurin inhibitors (cyclosporine, 3.6 mg/kg per day, or tacrolimus, 0.1 mg/kg per day; Table 1) at the same dosage as before enrollment for a month. Starting at 30 days, the prednisone dose had to be tapered off by 0.3 mg/kg per week if proteinuria was <1 g/d per m². After 2 weeks from the prednisone withdrawal, the calcineurin inhibitor dose had to be decreased by 50% and treatment stopped after 2 additional weeks.

Outcomes and Follow-up

Children were seen by the nephrologist responsible for the study at the beginning and at the end of the study (3 months), and as many times as necessary. Study coordinators maintained ongoing contact with the children and the families to monitor clinical status and report potential adverse events. The family pediatrician contacted the primary nephrologist for data reporting and clinical update. At baseline and after 3 months, proteinuria was determined at a central laboratory. Kidney function, plasma proteins, cell blood counts, and cholesterol were obtained monthly. The primary efficacy measure was the percentage change in daily proteinuria at 3 months by treatment group (study end). Patients treated with rituximab were further monitored for 15 months to ascertain medium-term safety of the drug. Patients in the control group were offered alternative therapies after the completion of the trial.

Pharmacokinetics Study

Serum samples were collected from patients assigned to rituximab immediately before and after 15 minutes and 24 hours after each infusion. Serum samples from all time points were kept frozen at –20°C until analysis, which was carried out within 3 months of sampling. Serum concentrations were evaluated by a very sensitive ELISA. For comparison, kinetics data were obtained in adults with different clinical
conditions who required rituximab infusion (22 with lymphoproliferative disorders, 22 with follicular non-Hodgkin lymphoma, and 14 with autoimmune diseases).

**Statistical Analyses**

We estimated that with 30 participants (the anticipated recruitment rate), we could detect a reduction in proteinuria by at least 70% at 3 months between treatment groups as statistically significant at a two-sided $P$ value of 0.05, with a power of 90%. We assumed a log-normal distribution of the response, with a coefficient of variation of 1.5 on the original scale (mean ± SD, 3 ± 4.5 g/d per m²), and a geometric mean ratio of 0.3 as the superiority margin. The estimation accounted for a 5% risk for withdrawals. The primary outcome was analyzed according to the intention-to-treat principle. Three-month log-transformed proteinuria was modeled using an analysis of covariance model with log-transformed baseline proteinuria as a covariate and treatment as the main effect. Prespecified secondary analyses tested the modification effect of previous sensitivity to standard therapy (partial or full remission). Missing values at 3 months in patients who did not complete the study were replaced by carrying forward their last available value (intention-to-treat analysis). Analyses were performed with Stata software, version 11.2 (Stata Corp., College Station, TX), and R 2.13.0 (http://www.R-project.org).
