ABSTRACT

Expression of thioredoxin-interacting protein (TxNIP), an endogenous inhibitor of the thiol oxidoreductase thioredoxin, is augmented by high glucose (HG) and promotes oxidative stress. We previously reported that TxNIP-deficient mesangial cells showed protection from HG-induced reactive oxygen species, mitogen-activated protein kinase phosphorylation, and collagen expression. Here, we investigated the potential role of TxNIP in the pathogenesis of diabetic nephropathy (DN) in vivo. Wild-type (WT) control, TxNIP−/−, and TxNIP+/− mice were rendered equally diabetic with low-dose streptozotocin. In contrast to effects in WT mice, diabetes did not increase albuminuria, proteinuria, serum cystatin C, or serum creatinine levels in TxNIP−/− mice. Whereas morphometric studies of kidneys revealed a thickened glomerular basement membrane and effaced podocytes in the diabetic WT mice, these changes were absent in the diabetic TxNIP−/− mice. Immunohistochemical analysis revealed significant increases in the levels of glomerular TGF-β1, collagen IV, and fibrosis only in WT diabetic mice. Additionally, only WT diabetic mice showed significant increases in oxidative stress (nitrotyrosine, urinary 8-hydroxy-2-deoxy-guanosine) and inflammation (IL-1β mRNA, F4/80 immunohistochemistry). Expression levels of Nox4-encoded mRNA and protein increased only in the diabetic WT animals. A significant loss of podocytes, assessed by Wilms’ tumor 1 and nephrin staining and urinary nephrin concentration, was found in diabetic WT but not TxNIP−/− mice. Furthermore, in cultured human podocytes exposed to HG, TxNIP knockdown with siRNA abolished the increased mitochondrial O2− generation and apoptosis. These data indicate that TxNIP has a critical role in the progression of DN and may be a promising therapeutic target.

Diabetic nephropathy (DN), a microvascular complication of diabetes mellitus, is the most frequent cause of ESRD in developed countries.1–3 In DN, hyperglycemia contributes to the morphologic alterations of the glomerular filtration barrier and loss of podocytes, ultimately leading to impairment of renal filtration.1,2 Although chronic hyperglycemia is the major cause, the detailed molecular pathogenesis of DN remains unclear.3

Among many pathogenic factors, an excessive production of reactive oxygen species (ROS) is thought to be a major contributor.1,4–6 The presence of excess ROS leads to the oxidation of proteins, DNA, and lipids, consequently deranging their configuration and function.7,8 In addition, by inhibiting glycolytic flux at the level of glyceraldehyde phosphate dehydrogenase, increased oxidative
stress drives glucose metabolic pathways; these pathways up-regulate signals triggered by advanced glycation endproducts, protein kinase C, and O-GlcNAcylation, which induce the pathologic changes seen in DN.6,8

One protein relevant to the regulation of ROS, which is markedly upregulated by high glucose (HG) in various cell types, is thioredoxin-interacting protein (TxNIP), also known as vitamin D upregulated protein 1 or thioredoxin binding protein.9–13 Under HG conditions, TxNIP has been implicated in impairing ROS scavenging by binding to and attenuating the antioxidant action of thioredoxin, a ubiquitous oxidoreductase.14 In addition, we recently reported that TxNIP enhances HG-induced mitochondria-derived \( \text{O}_2^\cdot\) (superoxide) as well as cellular ROS, at least in part, by augmenting the mitochondrial and cytosolic NADPH oxidase isoform, Nox4, in cultured mesangial cells.15 Thus, by increasing the generation and decreasing the degradation of ROS, HG-induced TxNIP may contribute to glucotoxicity, as observed by others and our group in pancreatic \( \beta \) cells.13,16,17

To elucidate the role of TxNIP in the pathogenesis of DN \textit{in vivo}, we explored the action of TxNIP in the diabetic kidney of wild-type (WT) and TxNIP\(^{-/-}\) (knockout [KO]) mice. In streptozotocin (STZ)-induced diabetic mice we found that, unlike in WT, indicators of renal injury and dysfunction such as albuminuria, proteinuria, serum cystatin C, and serum creatinine levels were not increased in diabetic TxNIP KO mice. Furthermore, histopathologic features of DN, such as effacement of podocyte foot processes and reduction in number of podocytes, thickening of the glomerular basement membrane (GBM), expansion of the mesangial matrix, and glomerulosclerosis, were all markedly attenuated in the diabetic KO, as were markers of ROS and inflammation. These data indicate that TxNIP deficiency protects against the renal complications of diabetes.

### RESULTS

**TxNIP Deficiency Prevents Albuminuria in STZ-Induced Diabetes and Loss of Renal Function**

To investigate the role of TxNIP in DN, we induced type 1 diabetes in TxNIP\(^{+/+}\) (WT) and TxNIP\(^{-/-}\) (KO) mice for 24 weeks. Results of the blood profile, fluid balance, renal measures, and BP are shown in Tables 1 and 2. Equivalent degrees of hyperglycemia, assessed by glucose concentrations and hemoglobin A\(_{1C}\), were achieved (Table 1). Furthermore, water consumption and urinary fluid excretion were similarly elevated (Table 2). Serum insulin levels were significantly decreased by diabetes but not different between WT and TxNIP KO. Body weights tended to be higher in TxNIP\(^{-/-}\) mice but were lower in both diabetic groups (\( P=NS \)). Kidney weight/body weight ratios tended to be increased in the diabetic state.

Serum lactate was elevated in the KO mice in the diabetic state, consistent with impaired mitochondrial glucose metabolism.15 BPs were lower in both diabetic groups, likely reflecting a decrease in volume contraction due to fluid loss (Table 2).

Renal measures were assessed 1 week before euthanasia (23 weeks). Albumin, albumin-to-creatinine ratio, and protein increased significantly in the urine of diabetic TxNIP WT mice but not in the TxNIP KO mice (Figure 1, A–C). Similarly, serum cystatin C, a marker of GFR that is not influenced by extrarenal factors, such as muscle mass, dietary protein, sex, and age (Figure 1D),18 and serum creatinine (Figure 1E) were significantly augmented only in the diabetic TxNIP WT mice. These findings suggest that a lack of TxNIP protects the kidneys from the glomerular manifestations of DN.

We performed similar experiments in TxNIP-deficient Hcb-19 mice (Supplemental Table 1). In the nondiabetic state, these Hcb-19 mice manifested increased body weight along with an absolute increase in kidney weight (but not kidney weight-to-body weight ratio) and an increased albumin-to-

creatinine ratio (Supplemental Table 1). However, while relative kidney weight was increased by diabetes in both groups, the TxNIP-deficient Hcb-19 mice showed no increase in albuminuria from baseline in contrast to C3H controls (Supplemental Table 1). Of interest, diabetic TxNIP-HET (TxNIP+/+) mice were also protected from diabetes-induced albuminuria (Supplemental Figure 1). While TxNIP mRNA in the diabetic TxNIP-HET mice was only approximately 50% that of diabetic WT, this still represented a marked increase compared with nondiabetic controls or TxNIP-HET mice (Supplemental Figure 2).

### Lack of TxNIP Protects Mice from Diabetes-Induced Renal Fibrosis and Extracellular Matrix Accumulation

The pathologic characteristics associated with DN in glomeruli were examined. Glomerular collagen IV (Figure 2, A–D) and TGF-β (Figure 2, E–H), key pathologic hallmarks, were significantly elevated (6- and 8.5-fold, respectively) in the diabetic WT mice compared with nondiabetic controls (Figure 2, Q and R). While the staining of these proteins tended to be lower in the nondiabetic TxNIP KO mice compared with WT mice (P=NS), there was a marked protection from the effects of diabetes in the KO mice with minimal increases (P=NS) in collagen IV (Figure 2, C, D, O) and TGF-β (Figure 2, G, H, R). Similarly, the degree of interstitial fibrosis, detected by Masson trichrome staining, was markedly augmented in the diabetic WT mice (Figure 2, I, J, S) but not altered in diabetic TxNIP KO mice (Figure 2, K, L, S). Glomerular extracellular matrix expansion, assessed by periodic acid-Schiff (PAS)–positive area (Figure 2, M, N, T) and glomerular volume (Table 2), were significantly increased only in the diabetic WT mice (Figure 2, O, P, T, and Table 2). The results in our studies of C3H (TxNIP+/+) and Hcb-19 (TxNIP-deficient) mice were consistent with those in TxNIP KO mice: namely, that diabetes increased glomerular PAS, collagen IV, and TGF-β staining in C3H mice but that these outcomes were attenuated in the Hcb-19 mice (Supplemental Figure 3, A–F). We also noted that partial TxNIP deficiency in the TxNIP-HET mice protected against the diabetes-induced renal profibrotic state (Supplemental Figure 4). These results support our15 and Kobayashi and colleagues19 observations that high glucose-stimulated collagen accumulation in cultured mesangial cells requires TxNIP and indicate that TxNIP is necessary for the induction of extracellular matrix deposition and renal fibrosis in diabetes.

### Reduction in Podocyte Number and Increased Urinary Nephrin Is Not Observed in Diabetic TxNIP KO Mice

Podocytes function as part of the normal glomerular filtration barrier.20 Podocyte numbers decline in DN, and this decrease signals progression to advanced disease.1,2,21-23 Thus, the numbers of podocytes were determined by staining for (Wilms’ tumor antigen-1 (WT-1), a transcription factor restricted to podocytes.24 The podocyte number per glomerulus was determined as described in the Concise Methods section to correct for changes in glomerular volume. The number of podocytes decreased significantly in diabetic WT mice, while in the TxNIP KO mice diabetes caused a minimal decrease (P=NS) (Figure 3A). These data were confirmed by staining for nephrin, another marker of podocytes (Supplemental Figure 5). Podocyte loss, associated with apoptosis, has been accompanied by increased urinary excretion of nephrin, a signal transducing and adhesion protein localized to the slit diaphragm.24 Total 24-hour urinary nephrin showed a marked increase caused by diabetes in WT but no significant change in TxNIP KO mice (Figure 3B).

### Podocyte Foot Process Effacement and Increased Glomerular Basement Membrane Thickness Are Observed in Diabetic WT but Not in TxNIP KO Mice

Thickening of the GBM and effacement of foot processes were major early ultrastructural changes observed by electron microscopy in DN.1,2 As shown in Figure 4, A and B, GBM thickness increased significantly in the diabetic WT mice but did not change in the diabetic TxNIP KO. Similarly, effacement of the podocyte foot processes was observed only in diabetic WT mice (Figure 4, A and C). In the TxNIP-HET mice, while we did not observe a significant effect of diabetes...
on podocyte foot process effacement, GBM thickening increased significantly ($P<0.01$) (Supplemental Figure 6). Taken together, these results demonstrate that TxNIP contributes to the structural damage of the glomerular filtration barrier during DN.

**TxNIP Mediates the Augmented Renal ROS/Reactive Nitrogen Species and Inflammation in Diabetic Mice**

ROS, reactive nitrogen species, and inflammation are reported to contribute to the progression of DN.\(^{25}\) We previously reported that TxNIP-deficient cultured mesangial cells are resistant to HG-induced stimulation of ROS.\(^{15}\) Therefore, we explored the involvement of TxNIP in the elevation of ROS, marked by urinary (8-hydroxy-2-deoxyguanosine [8-OhdG]), reactive nitrogen species (nitrotyrosine staining), and inflammation *in vivo*. Expression of nitrotyrosine was significantly increased in the glomeruli of diabetic WT mice (5.6-fold), but no change was observed between the nondiabetic and diabetic KO mice (Figure 5A). Similarly, urinary 8-OhdG levels, an indicator of oxidative DNA damage, was significantly increased in the WT diabetic mice and unchanged in the diabetic KO mice (Figure 5B).

Of interest, while urinary 8-OhdG was not altered by diabetes in the TxNIP-HET mice, nitrotyrosine staining was significantly increased (Supplemental Figure 7), suggesting that hyperglycemia can induce a degree of oxidative/nitrosative stress in the presence of lower amounts of TxNIP.

Because we found that TxNIP contributes to the increased expression of the NADPH oxidase isoform Nox4 in cultured mesangial cells,\(^{15}\) we examined this in our *in vivo* model. Both Nox4 protein (glomerular) and Nox4 mRNA (renal cortex) were significantly elevated only in the diabetic WT mice (Figure 5, C and D), supporting our *in vitro* findings. This was confirmed in the diabetic C3H (control) and Hcb-19 (TxNIP-deficient) mice (Supplemental Figure 3, G and H). Of interest, the oxidative/nitrosative stress and induction of Nox4 was also attenuated in the tubules of the diabetic KO mice (Supplemental Figure 8).

To assess the degree of glomerular macrophage infiltration and inflammation, we stained for the macrophage marker F4/80. F4/80 staining was markedly increased in the glomeruli of WT diabetic mice compared with nondiabetic controls (7.13±0.52% versus 0.16±0.03% of the total glomerular area) (Figure 6A). In addition, the mRNA expression of *IL1B* was significantly increased in the renal tissue of diabetic WT animals, while no significant change was observed in the diabetic KO (Figure 6B); this finding is consistent with reports that TxNIP, in association with the NLRP3 inflammasome, contributes to the production of the mature form of IL-1β.\(^{26,27}\) In the case of TNF-α expression, only a modest increase occurred in the diabetic WT mice, but no change was seen in the diabetic KO (Figure 6C). Of interest, the urinary neutrophil gelatinase-associated lipocalin (NGAL or lipocalin-2) level, an early biomarker of DN and acute renal injury,\(^{28}\) was significantly augmented only in the diabetic WT (Figure 6D). The TxNIP-HET mice showed a lesser but significant increase
Figure 2. Diabetic TxNIP^{−/−} mice do not develop mesangial matrix expansion and renal fibrosis. Renal fibrosis and mesangial matrix expansion in nondiabetic and diabetic TxNIP WT and KO mice. Representative images of renal fibrosis assessed by collagen IV (A–D) and TGF-β (E–H), as well as renal interstitial fibrosis (I–L; blue-green color detected by Masson trichrome staining). Mesangial matrix expansion was detected using PAS staining (M–P). Quantitation, determined by Visiomorph software (MSH), is shown in the graphs in
in inflammatory cell infiltration in the presence of diabetes, manifested by increased F4/80 staining (Supplemental Figure 9).

**TxNIP Promotes HG-Induced Mitochondrial O$_2^-$ and Apoptosis in Cultured Podocytes**

Our observations of protection from diabetes-mediated podocyte loss in TxNIP KO mice and the recently reported elevated levels of TxNIP in podocytes in DN suggest cell autonomous effects. HG increased the protein levels of TxNIP by 2.4±0.26-fold (P<0.001) (Figure 7E) in cultured human podocytes. HG also significantly stimulated mitochondrial O$_2^-$ generation (Figure 7A) and the mitochondrial membrane potential (Figure 7B) determined by MitoSox and JC-1, respectively. TxNIP knockdown in HG markedly inhibited these effects, associated with a concomitant increase in lactate production (Figure 7C); this is consistent with decreased mitochondrial TCA cycle flux and increased glycolysis. Of note, HG-induced cultured podocyte apoptosis was also blocked by TxNIP small interfering RNA (siRNA) (Figure 7, D and E).

**DISCUSSION**

DN accounts for almost one third of all cases of ESRD and, with the global “epidemic” of diabetes, has become a major health burden. Current attempts to normalize glycemia, control BP, and maintain blockade of the renin-angiotensin system have not eliminated DN or the need for dialysis and/or renal transplantation. Thus, it is essential to identify novel drug targets and more effective therapy.

Several studies have implicated the protein TxNIP as having a potential role in pathogenesis. First, we and others observed that TxNIP is a mediator of the increased collagen accumulation induced by HG in cultured mesangial cells. Second, TxNIP is increased in human diabetic kidney. Third, a correlation between protection from DN by the antifibrotic agent tranilast and the angiotensin receptor blocker telmisartan were correlated with a decrease in renal TxNIP in rodents. However, none of these reports demonstrated a clear pathogenic role for TxNIP in DN in vivo.

In the present study, we used two mouse models of TxNIP deficiency, Hcb-19, which harbors a spontaneous mutation, and TxNIP$^{-/-}$ (KO), with a targeted gene deletion. Both TxNIP-deficient mouse strains showed significant protection from DN. There was no or minimal increase in diabetes-induced albuminuria or in the pathologic changes of mesangial expansion, expression of TGF-β, collagen IV, and interstitial fibrosis.

Although the nondiabetic Hcb-19 mice manifested albuminuria in the absence of the morphologic changes observed in the diabetic state, the nondiabetic TxNIP$^{-/-}$ mice were identical to controls in all renal measures studied. The cause of the baseline albuminuria in Hcb-19 mice is not clear, but this did not mask the protection from the diabetes-induced changes measured. Electron microscopic analysis revealed a significant attenuation of podocyte foot process effacement and GBM thickening in the diabetic TxNIP$^{-/-}$ mice. These are well characterized findings of early DN in mice. At the same time, glycemia and BP were similar in WT and TxNIP$^{-/-}$ diabetic mice. While TxNIP deficiency has been reported to protect against STZ-induced diabetes by our group and others, we developed a two-course STZ injection protocol to generate equivalent hyperglycemia. Thus, differences in glycemia or BP do not explain protection from DN.

The pathogenesis of diabetes complications, including DN, has been proposed to be initiated by excess generation of ROS by mitochondria stimulated by HG. The consequent change in cellular redox state is thought to inhibit glyceraldehyde-3-phosphate dehydrogenase, a redox-sensitive enzyme upstream of pyruvate synthesis that results in increased glucose metabolism via several different pathways, which mediate its “toxicity.” These include formation of advanced glycation endproducts, activation of protein kinase C, and increased flux through the polyol and hexosamine biosynthesis pathways.

We and others have implicated TxNIP in this initiating event. In cardiomyocytes and mesangial cells from TxNIP-deficient mice, decreased mitochondrial glucose metabolism concomitant with increased glycolysis and lactate production has been observed. Furthermore, HG did not stimulate mesangial cell mitochondrial membrane potential or ROS generation in the TxNIP-deficient state, while adenoviral mediated overexpression of TxNIP restored these responses. These data are consistent with the modestly elevated circulating lactate levels in TxNIP$^{-/-}$ mice and the marked increase observed in the diabetic state (Table 1).

The mechanism by which TxNIP regulates mitochondrial metabolism is not clear, but it has been proposed that TxNIP may regulate pyruvate dehydrogenase, thus promoting TCA cycle flux and oxidative phosphorylation. Evidence for a defect in ROS generation in vivo was manifested by the lack of increase in urinary 8-OHdG in the TxNIP$^{-/-}$ diabetic mice in contrast to diabetic WT (Figure 5B). This was supported by the reduced mitochondrial membrane potential and ROS production in TxNIP-silenced cultured podocytes exposed to HG (Figure 7, A–C). In addition, glomerular and tubular staining for nitrotyrosine, which is closely associated with oxidative stress, was increased by diabetes only in WT mice (Figure 5A, Supplemental Figure 8A, and Supplemental 8C). Apart from mitochondria, elevated ROS in the hyperglycemic/diabetic state results from augmented NADPH oxidase activity. At least three NADPH oxidase isomers have been identified in the bottom panels (Q–T). Results are mean±SEM (n=5 mice/condition). *P<0.05; **P<0.01; and ***P<0.001 diabetic WT mice versus nondiabetic WT; #P<0.05 and ###P<0.001 diabetic WT versus diabetic TxNIP KO mice. Original magnification, ×400.
Several measures predictive of progression of DN were assessed. Thus, podocyte loss, increased 24-hour urinary nephrin and NGAL excretion were observed in the diabetic WT but not in the TxNIP\(^{-/-}\) mice. Protection from podocyte loss in vivo was supported by inhibition of HG-induced apoptosis observed in the TxNIP-silenced cultured human podocytes (Figure 7, D and E). In addition, evidence for a decrease in GFR and renal function after 6 months of diabetes was demonstrated by increases in serum cystatin C and serum creatinine in the diabetic WT mice. However, these variables were not altered by diabetes in the TxNIP\(^{-/-}\) mice. These findings are consistent with an important role of TxNIP in the initiation and progression of DN.

TxNIP has also been implicated in the innate immune response, associated with NLRP3 complex signaling to caspase-1-mediated cleavage and release of IL-1\(\beta\), activation of NF-\(\kappa\)B, and increased cytokine expression.\(^{10,26,27}\) Increased IL-1\(\beta\) expression has also been reported to be stimulated by TxNIP.\(^{27}\) Furthermore, infiltration of macrophages and inflammation has been documented in DN.\(^{7,25}\) In TxNIP\(^{-/-}\) mice, glomerular macrophage infiltration in the diabetic state was decreased compared with WT (Figure 6A), and kidney cortex IL-1\(\beta\) mRNA was increased only in diabetic WT (Figure 6B).

Diabetic heterozygous TxNIP\(^{+/+}\) (HET) mice showed a partial protection from several of the preceding endpoints of DN (Supplemental Figures 1, 4, 6, 7, and 9). These mice had a significant increase in renal TxNIP mRNA induced by diabetes, which was less than that in WT mice but clearly far greater than in the nondiabetic state (Supplemental Figure 2). We noted that the inhibition of pathologic changes associated with fibrosis in the diabetic HET mice was, in general, greater than the partial inhibition of oxidative stress and inflammation. Thus, whether the lower level of TxNIP inhibits progression from early to more advanced DN or significantly delays (but does not completely block) progression requires further study. Taken together, these data in diabetic TxNIP\(^{-/-}\), TxNIP\(^{+/+}\), and Hcb-19 mice indicate that TxNIP is a key mediator of oxidative stress and the pathologic markers of DN. Because these mouse models lack TxNIP in all cells and tissues, it is not possible to completely exclude a contribution of systemic effects (e.g., decreased inflammation) to protection from DN. However, our data in podocytes and in mesangial cells,\(^{13,17}\) as well as in cardiomyocytes,\(^{38,46}\) \(\beta\) cells,\(^{13,17}\) and, recently, renal proximal tubular cells,\(^{47}\) indicate major cell autonomous protective effects of TxNIP deficiency. The precise contribution and role of TxNIP in various cell types in the kidney to DN (i.e., endothelial, mesangial, epithelial [podocytes] and tubular cells) remain to be documented, along with tissue-specific KO mouse models.

---

Defect in Nox4 upregulation by HG.\(^{15}\) The present in vivo data support these observations, showing that TxNIP\(^{-/-}\) diabetic mice, in contrast to WT, did not display an increase in kidney cortex Nox4 mRNA or glomerular and tubular staining for Nox4 protein (Figure 5, C and D, Supplemental Figure 8, A and B).

---

**References**

In summary, to our knowledge this is the first *in vivo* study of DN in TxNIP-deficient animal models. The results indicate that a lack of TxNIP protects against DN and support *in vitro* data in various cell types that upregulation of TxNIP by HG is a key mediator of early oxidative stress and a trigger for the development and progression of DN. The downregulation of TxNIP and/or interference with its function may be an effective therapeutic strategy. The data in the diabetic heterozygous TxNIP+/− mice suggest that TxNIP would have to be maintained at or lowered to near basal levels to achieve complete protection. Further work in different diabetic mouse models and in specific renal cell types is warranted.

**CONCISE METHODS**

**Mice, Reagents, and Metabolic Studies**

TxNIP WT (TxNIP+/+), TxNIP KO (TxNIP −/−), and TxNIP HET (TxNIP +/+ ) mice (kindly provided by R.T. Lee, Harvard University), as well as Hcb-19 mice (lacking TxNIP because of a spontaneous mutation) and its control C3H/DiSnA (kindly provided by the late R.A. Davis, San Diego State University), were housed under standard conditions and provided chow and water *ad libitum* at the Animal Resource Center, University Health Network (UHN, Toronto, ON, Canada). All the experimental procedures were approved by the...
Animal Care Committee of the UHN and were followed according to the guidelines of the Canadian Council of Animal Care. Diabetes was induced in 10 mice per group at 6–8 weeks of age by intraperitoneal injections of STZ (40 mg/kg in fresh 0.1 M sodium citrate buffer, pH 4.5) daily for 5 days (http://www.diacomp.org), followed 5 weeks later by a second round of five STZ injections. Control (nondiabetic)
groups received citrate buffer. Blood glucose levels were monitored with a glucometer (FreeStyle Lite, Alameda, CA) monthly throughout the experimental period.

Twenty-three weeks after STZ injections, the animals were individually placed in Tecniplast metabolic chambers for 24 hours to determine the volume of urine excretion and water consumption.

Figure 6. TxNIP−/− mice lack a renal inflammatory response in response to chronic hyperglycemia. Inflammatory markers in the renal tissues from nondiabetic and diabetic TxNIP WT and KO mice. (A) Representative images of F4/80 (marker for macrophages)-positive staining in the glomeruli and quantification from n=5 mice/condition. Expression of cytokine mRNA, (B) IL-1β, and (C) TNF-α, corrected for actb and normalized to nondiabetic WT in renal cortex (n=5 mice/condition). (D) Twenty-four-hour urinary NGAL levels (ng) from 6 to 7 mice/condition. Results are mean±SEM. *P<0.05 and **P<0.01 diabetic WT mice versus nondiabetic WT; and #P<0.05 and ##P<0.01 diabetic WT versus diabetic TxNIP KO mice.
After measurement of urine volume, urine was centrifuged at 1000 rpm for 1 minute to remove any debris and then frozen at 

280°C for further analysis.

At 24 weeks mice were subjected to BP, and the remaining mice were euthanized for renal tissues and blood as described below.

**Blood Profile and Urinalysis**

At the time of euthanasia, blood was removed via cardiac puncture. Samples of whole blood and plasma and serum were provided to the Pathology and Lab Medicine (PLM) Department, Mount Sinai Hospital (MSH), Toronto for the following determinations: blood glucose, plasma glucose, Hemoglobin A\textsubscript{1c}, hemoglobin, red blood cell count, and white blood cell count (Table 1). The instruments used to assess these measures were Roche Modular, Cobas Integra 400, and Sysmex XE-2100 Automated Hematology System. Serum insulin (ELISA kit from EMD Millipore), serum lactate and ketones (kits from Abcam, Inc.), and serum cystatin C (Quantikine ELISA kit from R&D Systems) were measured according to the manufacturer’s guidelines and assessed using a Bio-Tek microplate reader and Gen5 software. Serum creatinine was measured using HPLC by the Hormone Assay and Analytical Services Core, Vanderbilt University School of Medicine (Nashville, TN).

Urinary assays for albumin, creatinine, and nephrin (kits from Exocell), NGAL (Alpco Diagnostics), and 8-OHdG (StressMarq Biosciences) were assessed according to the manufacturer’s guidelines. Protein concentration was measured using the Bio-Rad Protein Assay.

**Invasive Hemodynamics**

Hemodynamics were performed on mice under 1% isoflurane anesthesia using a 1.4-F Millar pressure-transducing catheter introduced through the right common carotid artery. Data were collected and analyzed using AcqKnowledge (version 2.8.1; BIOPAC Systems, Montreal, QC, Canada) as

Figure 7. TxNIP knockdown in cultured human podocytes exposed to high glucose inhibits the increased mitochondrial O$_2^-$, membrane potential, and apoptosis. Knockdown of TxNIP attenuates mitochondrial O$_2^-$, and membrane potential and apoptosis in cultured human podocytes. Podocytes were transfected with 50 nM TxNIP-specific siRNA (siTxNIP) or universal negative control siRNA (scrambled, scr) for 24 hours and then incubated in 5 mM normal glucose (NG) or 25 mM HG for 48 hours. (A and B) Mitochondrial superoxide formation and mitochondrial membrane potential were assessed by confocal microscopy using MitoSox and JC-1 dyes, respectively (n=3), with the quantification illustrated as graphs in the bottom panel. (C) Lactate concentration in the cell culture media (n=6). Apoptosis in podocytes treated with NG/HG and scr/siTxNIP was assessed with (D) TUNEL assay and (E) cleaved caspase-3 protein expression in three independent experiments. Results are mean ± SEM. *P<0.05; **P<0.01; and ***P<0.001 versus scr NG; $P<0.05$ and $^{#P}<0.001$ versus scr 48-hour HG.

---

previously described. All measurements were performed in triplicate and averaged for each animal (n=3 for HET and n=6 for WT and KO groups).

**Tissue Histology and Immunohistochemistry**

Kidneys were immediately harvested, fixed in 10% buffered formalin, and embedded in paraffin; 3-μm sections were subjected to PAS staining; Masson trichrome staining; and WT-1 (1:500; Santa Cruz Biotechnology), F4/80 (1:500; Serotec), and Nitrotyrosine (1:800; Chemicon) staining. Staining of sections using the antibodies directed against collagen IV (1:2500; Rockland), TGF-β (1:2500, Acris-antibodies), nephrin (1:1000; Abnova), and Nox4 (1:2500; Santa Cruz Biotechnology) was performed by following the procedures previously described. Quantitative analysis was performed on 50 glomeruli per kidney section with the aid of Visiomorph software (PLM Department, MSH, Toronto, ON).

**Glomerular Volume**

Glomerular volume was calculated using the formula GV=(β/κ)GA^{3/2}, where β=1.38 (the shape coefficient of spheres as assumed model glomeruli) and κ=1.10, the size distribution coefficient. Glomerular area was determined using Visiomorph software.

The number of WT-1-positive cells per glomerulus (i.e., glomerular cell volume) was counted as previously described by the Animal Models of Diabetic Complications Consortium (http://www.diacomp.org) and Sanden et al. (2003). Briefly, WT-1-positive nuclei (counted manually) and glomerular area (Visiomorph software) were assessed in 50 random glomeruli (outer to inner cortex) in two kidney sections of different thickness (3 and 9 μm). From the data, the average podocyte number/glomerular area (P/GA) was calculated for both sections and the difference, P/GA Δ, was determined. The average glomerular volume/podocyte, GV/P, was calculated by dividing the difference in section thickness, 6.3, by the P/GA Δ. Then, using the Weibel formula, the mean glomerular volume was calculated. The podocyte number per glomerulus was obtained by dividing the mean glomerular volume by the glomerular volume/podocyte (GV/P).

**Cell Culture**

Immortalized human podocytes (a kind gift of R. Coward and M. Saleem, University of Bristol) transfected with the temperature-sensitive simian vacuolating virus 40 (SV40) gene were grown in RPMI 1640 media supplemented with 10% FBS and 1% insulin-transferrin-selenium at 33°C until they were 70%–80% confluent. They were then thermo-switched to 38°C to silence the SV40 gene and allowed to differentiate for 14–20 days before experiments. Transfection was conducted with 50 nM of universal negative control (scrambled siRNA) or TxNIP siRNA (catalog no. TXNIPHSS173789, Invitrogen) for 24 hours, followed by 48 hours of HG treatment in 0.2% FBS-containing medium. After this period, the cells were harvested for Western blot or stained for immunofluorescence studies.

**MitoSox and JC-1 Immunofluorescence**

Studies on the transfected podocytes with MitoSox and JC-1 were carried out as previously described.
**Lactate Assay**

Lactate in the cell culture medium was assessed using a lactate colorimetric assay kit from Abcam, Inc. as previously described.15

**Terminal Deoxynucleotidyl Transferase-Mediated Transferase–Mediated Digoxigenin-Deoxyuridine Nick-End Labeling Immunofluorescence**

Terminal deoxynucleotidyl transferase–mediated transferase–mediated digoxigenin–deoxyuridine nick-end labeling (TUNEL) assays were performed to detect apoptotic cells after various treatments. The DeadEnd Fluorometric TUNEL System (Promega) was used according to the manufacturer’s instructions. Briefly, cells were cultured on glass coverslips and differentiated at 38°C for 14 days. After treatment, they were fixed in 4% paraformaldehyde for 25 minutes at room temperature. They were subsequently permeabilized with 0.2% Triton X-100 in PBS, equilibrated in EQUILIBRIUM BUFFER, and incubated with 50 μl of TUNEL reaction mixture for 1 hour in a humidified chamber at 37°C. Saline-sodium citrate (2X) was used to stop the reaction, and 300 nM DAPI was added to stain for nuclei. Coverslips were then mounted on microscope slides and viewed under a fluorescence microscope.

**Immunoblotting**

Western blot was performed as previously described.15 Briefly, protein concentrations were determined with the modified Lowry microassay (Bio-Rad). After the samples were boiled in 4X sample buffer, 20 μg of protein was separated by 10%–15% SDS-PAGE, transferred onto nitrocellulose membranes, and blocked with 5% milk/Tris-buffer saline with 0.1% Tween 20. The primary antibodies used were cleaved nitrocellulose membranes, and blocked with 5% milk/Tris-buffer saline with 0.1% Tween 20. The primary antibodies used were cleaved caspase-3 (1:500; Cell Signaling Technology), TxNIP (1:1000; MBL), and β-actin (1:10,000; Santa Cruz Biotechnology), and the secondary antibodies (1:4000) were anti-rabbit IgG horseradish peroxidase conjugate (Bio-Rad) and peroxidase-conjugated anti-mouse IgG (Jackson ImmunoResearch Laboratories). Immunoblots were visualized by the ECL detection system (KPL Mandel Scientific) and the densitometric analyses were conducted with ImageJ software (National Institutes of Health).

**Electron Microscopy**

Transmission electron microscopy was performed on renal cortical tissues from three mice per group (PLM Department, MSH). Nine fields per experimental condition were examined for GBM thickness.

**Quantitative Real-Time PCR**

Fifty milligrams of frozen renal cortex was sheared to powder using liquid nitrogen and then homogenized in 1 ml TRIzol reagent (Invitrogen) for RNA extraction. Purity and concentration of RNA were checked with a Nanodrop spectrophotometer (Thermo Fisher Scientific). cDNA synthesis was performed using M-MLV reverse transcription kit (Invitrogen). The resulting cDNA was then used for real-time PCR analysis using the Taqman Gene Expression System (Applied Biosystems). The gene-specific primers for mouse obtained from Applied Biosystems were as follows: mouse TxNIP (Mm00452393_m1), mouse nox4 (Mm00479246_m1), mouse IL-1β (Mm00434228_m1), mouse TNF-α (Mm0043260_g1), and the housekeeping gene–mouse actin (Mm00607939_s1). A standard curve was generated with diluted cDNA from the control group. A PCR reaction mix (25 μl/well) was prepared containing 10 μl of 300 ng/μl cDNA, 1.25 μl of double-distilled water, 1.25 μl of Taqman Gene Expression Primers, and 12.5 μl of Taqman Gene Expression Master Mix. The samples were loaded into an ABI Prism 96-well reaction plate and then run on an ABI Prism 7900HT sequence detection system. The values obtained were determined using SDS 2.3 software (ABI Prism 7900 HT) and then normalized to the expression of actin for each sample. The final values are expressed as fold of nondiabetic WT (control) group.

**Statistical Analyses**

Data are presented as mean±SEM, unless otherwise stated. Statistical significance was calculated using Graphpad Prism software, version 4.0 (Graphpad Prism, San Diego, CA) by one-way ANOVA, followed by the Newman-Keuls post hoc method for multiple comparisons. Comparison between two sets of samples was analyzed by t test. P<0.05 was considered to represent a statistically significant difference.

**ACKNOWLEDGMENTS**

The authors would like to thank Dr. R.T. Lee and J. Yoshioka (Harvard Medical School, Boston, MA) for providing mice and helpful discussion.

This work was supported by the Canadian Institutes of Health Research grants MOP97979 and PCN 49409 (to I.G.F.). A.S. was sponsored in part by a Novo Nordisk Studentship and UHN-Graduate Studentship from the Banting and Best Diabetes Centre, a Canada Graduate Scholarship (NSERC), and an Ontario Graduate Scholarship.

A portion of this work was presented at the 16th Annual Canadian Diabetes Association/Canadian Society of Endocrinology and Metabolism (CDA/CSEM) Professional Conference (Montreal, Quebec; October 17–20, 2013).

**DISCLOSURES**

None.
